Problem 1

Problem 1a (Programming Problem)

In this problem, you will write a Python or R function that automatically tunes black-box regression models. Your function should take as input:

- A learning algorithm, i.e., a function that takes as input a matrix $X \in \mathbb{R}^{n \times p}$ and a vector of responses $Y \in \mathbb{R}^n$ and returns a function that maps inputs to outputs, i.e., maps $\mathbb{R}^p$ into $\mathbb{R}$.
- Training data $X \in \mathbb{R}^{n \times p}$ and $Y \in \mathbb{R}^n$.
- A regularization method that belongs to the set $\{\text{Dropout}, \text{NoiseAddition}\}$.
- A positive integer M indicating the number of Monte Carlo replicates to be used if the method specified is `Dropout` or `NoiseAddition`.
- A positive integer K indicating the number of CV-folds to be used to tune the amount of regularization (e.g., $K = 5$ indicates five-fold CV).
- A criterion to be used to evaluate the method that belongs to the set $\{\text{MSE}, \text{MAD}\}$, where `MSE` encodes mean square error and `MAD` encodes mean absolute deviation.

Your function should output a predictive model that optimizes the specified criterion using the specified method. For example, if the function were called with `Dropout`, $M = 100$, $K = 10$ and `MSE`, it would find the amount of dropout (with $M = 100$ random dropout vectors per observation) that minimizes the ten-fold cross-validated MSE and return the learning algorithm trained with this amount of dropout.

Problem 1b (Ambiguity Abounds)

Now you will implement (your own) version of a robust noise-addition algorithm.

Let F be a class of regression models and let

$$L_n(X, Y; f) = \sum_{i=1}^{n} \{Y_i - f(X_i)\}^2$$

be the squared error loss. Suppose the black-box method computes

$$\hat{f}_n = \arg\min_{f \in F} L_n(X, Y; f).$$

Given $c \in \mathbb{R}^p$, define

$$U_c \triangleq \left\{ \Delta \in \mathbb{R}^{n \times p} \,\middle|\, \sum_{i=1}^{n} \Delta_{i,j}^2 \leq c_j, \quad j = 1, \ldots, p \right\}.$$

We want to approximate

$$\tilde{f}_{c,n}^r \triangleq \arg\min_{f \in F} \max_{\Delta \in U_c} L_n(X + \Delta, Y; f).$$

However, we do not have explicit access to F, only a black-box that will compute $\hat{f}_n$ on a given dataset. In other words, we can do:

```
model = MysteryLearningAlgorithm()
model.fit(X_train, Y_train)
y_predict = model.predict(X_test)
```

so we can fit and predict, but we have no idea what `MysteryLearningAlgorithm` is doing other than trying to minimize least squares over some class F.

Create and implement your own (approximate) algorithm for approximating the robust solution $\tilde{f}^r_{c,n}$. Your algorithm should take as input: (i) the training data; (ii) the constraint vector c; (iii) the black-box learning algorithm which has a `fit` and `predict` method; and, if needed, (iv) additional tuning parameters.

Code Submission

We take `RandomForestRegressor` as a black-box regression model for experiments. Below is the implementation code for this problem.

```python
import numpy as np
from sklearn.model_selection import KFold
from sklearn.metrics import mean_squared_error, mean_absolute_error
from sklearn.metrics import mean_squared_error
from sklearn.datasets import make_regression
from sklearn.ensemble import RandomForestRegressor
from sklearn.metrics import r2_score

# apply regularization: Dropout or Noise Addition
def regularize(X, method, param, M):
    X_reg = np.zeros_like(X)
    for _ in range(M):
        if method == 'Dropout':
            mask = np.random.binomial(1, 1 - param, size=X.shape)
            X_reg += X * mask
        elif method == 'NoiseAddition':
            noise = np.random.normal(0, param, size=X.shape)
            X_reg += X + noise
    return X_reg / M

# tune regularization for a blackbox regression model
def tune_blackbox_regression(learning_algorithm, X, Y, method, M, K, criterion):

```

Detailed Explanation

In this section, we present our robust tuning method for black-box regression models that addresses three key aspects: Black-box Optimization, Constrained Optimization, and Min-max Optimization. Specifically, we employs Monte Carlo sampling to approximate worst-case adversarial perturbations, then retrain the black-box model on the worst-case perturbed dataset. We also tune a regularization parameter (via dropout or noise addition) using cross-validation.

Black-Box Optimization

In our setting, the learning algorithm is treated as a black box. To optimize the regularization parameter, we use a grid search over a range of regularization parameters. For each candidate parameter, we employ K-fold ($K = 10$ in our experiment) cross-validation and compute an evaluation metric (MSE or MAD). The parameter that minimizes the cross-validated loss is selected. This derivative-free approach, relying solely on repeated evaluations of the loss, is well-suited for black-box optimization.

Constrained Optimization

The noise or dropout perturbation Δ must satisfy the quadratic constraints:

$$\sum_{i=1}^{n} \Delta_{i,j}^2 \leq c_j \quad \text{for each feature } j.$$

Our implementation enforces this constraint in the `generate_delta` function, where a candidate perturbation is first generated from a standard normal distribution. For each feature, we compute its ℓ_2-norm and, if necessary, scale the perturbation to ensure that the squared sum does not exceed c_j (by setting the norm to $\sqrt{c_j}$). This guarantees that every generated perturbation vector Δ lies within the allowed set U_c.

Min-Max Optimization

The robust model training objective is given by:

$$\tilde{f}^r_{c,n} = \arg\min_{f \in F} \max_{\Delta \in U_c} L_n(X + \Delta, Y; f).$$

Since we cannot directly solve this min-max problem due to the black-box nature of the learning algorithm, we approximate the inner maximization as follows:

1. **Monte Carlo Sampling:** We generate multiple random perturbations Δ that satisfy the constraint.
2. **Worst-Case Selection:** For each perturbation, we train a model and compute the loss. The perturbation that yields the highest loss (worst-case scenario) is selected.
3. **Robust Model Training:** Finally, the black-box model is retrained on the dataset perturbed by the worst-case Δ.

This approach effectively simulates an adversary that seeks to maximize the loss, thereby guiding the model to learn robustly.

Experiment Results

1. **Problem-1a:** The optimal regularization parameter is found to be **0.0644**, while Model-1a R^2 Score is **0.9549**.
2. **Problem-1b:** The worst-case loss identified during robust training is **724.8825**, while the Robust Model-1b R^2 Score is **0.9318**.

The results confirm that tuning the dropout parameter can significantly improve model performance. Additionally, the robust noise addition strategy provides resilience against adversarial perturbations, albeit with a slight decrease in R^2 compared to the tuned model.

Problem 2

Recall that the unilasso computes the lasso estimator subject to the constraint that the estimated coefficients match the sign of their uni- variate regression analogues. Given data $\{(\mathbf{X}_i, Y_i)\}_{i=1}^n$ comprising n independent copies of $(\mathbf{X}, Y)$ with $\mathbf{X} \in \mathcal{X} \subseteq \mathbb{R}^p$ and $Y \in \mathbb{R}$ the uni- lasso algorithm consists of the following steps.

1. For $j = 1, \ldots, p$ compute

$$\hat{\alpha}_{n,j,0}, \hat{\alpha}_{n,j,1} = \arg\min_{\alpha_0,\alpha_1} \sum_{i=1}^n (Y_i - \alpha_0 - \alpha_1 X_{i,j})^2 \tag{1}$$

   and for $i = 1, \ldots, n$ compute the jackknife coefficients

$$\hat{\alpha}^{-i}_{n,j,0}, \hat{\alpha}^{-i}_{n,j,1} = \arg\min_{\alpha_0,\alpha_1} \sum_{\ell \neq i}^n (Y_\ell - \alpha_0 - \alpha_1 X_{\ell,j})^2. \tag{2}$$

2. Compute $\hat{\boldsymbol{\theta}}_n^\lambda \in \mathbb{R}^{p+1}$ as the solution to

$$\min_{\theta \in \mathbb{R}^{p+1}} \sum_{i=1}^n \left\{ Y_i - \theta_0 - \sum_{j=1}^p \theta_j \left(\hat{\alpha}^{-i}_{n,j,0} + \hat{\alpha}^{-i}_{n,j,1} X_{i,j} \right) \right\}^2 + \lambda \sum_{j=1}^p |\theta_j| \tag{3}$$

   such that

$$\theta_j \geq 0, \quad j = 1, \ldots, p. \tag{4}$$

3. Set $\hat{\gamma}^\lambda_{n,0} = \hat{\theta}^\lambda_0 + \sum_{j=1}^p \hat{\theta}^\lambda_n \hat{\alpha}_{n,j,1}$ and $\hat{\gamma}^\lambda_{n,j} = \hat{\theta}^\lambda_n \hat{\alpha}_{n,j,1}$. The unilasso prediction model is given by the linear model

$$\mathbf{x} \mapsto \hat{\gamma}^\lambda_{n,0} + \sum_{j=1}^p \gamma^\lambda_{n,j} x_j. \tag{5}$$

2a. Implement the unilasso in python. It is recommended that you use either cvxopt or cvxpy (these are worth knowing anyway). Tuning should be done using k-fold cross-validated mean squared error. Verify empirically through a suite of simulated examples that unilasso solution computed by your code agrees in sign (here, zero is considered to agree in sign with both ± 1).

Ans: The Unilasso algorithm was implemented and verified through simulation studies (code can be found below). Cross-validation selected an optimal regularization parameter of $\lambda = 78.475$, which produced a sparse model with coefficients that accurately recovered the sign pattern of the univariate regression coefficients. The estimated coefficients closely matched the true values in our simulation, with $\hat{\gamma}^\lambda_{n,1} \approx 2.052$ (true value: 2.0), $\hat{\gamma}^\lambda_{n,3} \approx -1.521$ (true value: -1.5), and $\hat{\gamma}^\lambda_{n,5} \approx 0.963$ (true value: 1.0). Across five independent simulations with different random data, sign agreement was verified in all cases. This confirms that the unilasso estimator successfully satisfies the constraint that its estimated coefficients match the sign of their univariate regression analogues, as required by the algorithm definition.

2b. Construct a generative model with $p = 2m$ predictors such that the signs of m of the coefficients will (asymptotically) disagree in sign with their univariate regressions. You can give a mathematical construction/proof or a simulation example.

Ans: In this part, using a flipping-sign experiment, we demonstrate that univariate regression can be tricked when features are highly correlated. Setting the feature dimension $p = 2m$, each feature X_j is paired with a nearly identical copy X_{j+m} but assigned an opposite coefficient sign. Although these pairs produce nearly identical predictions, their univariate fits yield inconsistent signs, which can mislead unilasso. Specifically, unilasso relies on univariate slopes α_1 to determine each feature's direction; when strong correlations exist, one univariate regression might pick a positive slope while the other is negative, causing contradictory signs in the final multivariate solution. For the 10 feature dimensions in our experiment, we yield:

Table 1: Comparison of True Coefficients and Estimated Signs

Index	True Coefficient	Univariate Sign	Multivariate Sign
1	1	1	1
2	1	1	-1
3	1	-1	1
4	1	-1	1
5	1	-1	1
6	-1	1	-1
7	-1	1	1
8	-1	-1	-1
9	-1	-1	-1
10	-1	-1	-1

We can see univariate has recovers 50% signs correctly while muoltivariate recovers 80%. Cmparing univariate vs. multivariate signs, we see that unilasso often fails to recover the correct signs, even though it may still achieve low mean squared error.

2c. The soft-unilasso replaces step ii. above by constructing $\hat{\boldsymbol{\theta}}_n^{\lambda,\rho}$ as the solution to

$$\sum_{i=1}^{n}\left\{Y_i - \theta_0 - \sum_{j=1}^{p}\theta_j\left(\hat{\alpha}_{n,j,0}^{-i} + \hat{\alpha}_{n,j,1}^{-i}X_{i,j}\right)\right\}^2 + \lambda\sum_{j=1}^{p}|\theta_j| + \rho\sum_{j=1}^{p}[\theta_j]_-, \tag{6}$$

where $[u]_- = |u|1_{u\leq 0}$ is the negative-part operator. Implement the soft-unilasso tuning both λ and ρ using cross-validation. Verify via numerical experiment that it recovers the unilasso solution as $\rho \to \infty$.

Ans: We impelmented the soft-unilasso and proceed 4 simulations of rho values from $rho = 0.01$ to $rho = 10000$:

Table 2: Soft-Unilasso Coefficients for Different ρ

ρ	Coefficients									
0.01	-1.25×10^{-5}	0.6538	0.6554	-1.29×10^{-5}	0.4817	0.5871	0.4447	0.4996	0.4453	0.2814
1	-1.28×10^{-8}	0.6538	0.6554	-1.11×10^{-7}	0.4817	0.5871	0.4447	0.4996	0.4453	0.2814
100	1.29×10^{-10}	0.6538	0.6554	9.15×10^{-11}	0.4817	0.5871	0.4447	0.4996	0.4453	0.2814
10000	-1.33×10^{-7}	0.6538	0.6554	-2.65×10^{-7}	0.4817	0.5871	0.4447	0.4996	0.4454	0.2814

Discussion:

Although the soft-unilasso formulation is designed so that its solution converges to the uni-lasso as $\rho \to \infty$, our numerical implementation do not show an exact convergence, although yielding a good MSE (The result in the part d also verify the implementation). We believe it is because the additional penalty term $\rho\sum_{j=1}^{p}[\theta_j]_-$ enforces nonnegativity, but when the optimal θ_j are already near zero or positive, further increasing ρ has little impact.

2d. Conduct a simulation study comparing unilasso and soft-unilasso. Include examples based on 2b. where the unilasso should perform poorly because of sign disagreement.

Sim	Method	MSE	Sign Agreement	Lambda	Rho
0	Unilasso	0.009424	0.100	10.000000	-

	Soft-Unilasso	0.008552	0.500	0.464159	31.622777
9	Unilasso	0.014925	0.100	1000.000000	-
	Soft-Unilasso	0.014925	0.500	0.464159	1000.000000

Table 3: Simulation results comparing Unilasso and Soft-Unilasso across different settings.

Method	Avg MSE ± SE	Avg Sign Agreement ± SE
Unilasso	0.010425 ± 0.000565	0.180 ± 0.037
Soft-Unilasso	0.010526 ± 0.000567	0.500 ± 0.000

Table 4: Summary statistics for the performance of Unilasso and Soft-Unilasso.

We conducted a simulation study comparing Unilasso and Soft-Unilasso in settings with potential sign disagreements (as in 2b). The results show that both methods achieve similar MSE on average (0.010425 vs. 0.010526), but Soft-Unilasso consistently attains higher sign agreement (0.500 vs. 0.180). In fact, Soft-Unilasso outperforms Unilasso in 6 of 10 simulations by MSE, and in all 10 simulations by sign agreement. This suggests that although Unilasso can yield comparable predictive accuracy, its strict sign constraints may lead to suboptimal coefficient estimates. By contrast, Soft-Unilasso provides a more faithful representation of the underlying model's signs, aligning with the theoretical expectation that relaxing rigid sign matching can better capture true relationships.
